Abstract

We develop a practical approach to querying temporal data stored in temporal SQL:2011 databases through the semantic layer of OWL 2 QL ontologies. An interval-based temporal query language (TQL), which we propose for this task, is defined via naturally characterizable combinations of temporal logic with conjunctive queries. This foundation warrants well-defined semantics and formal properties of TQL querying. In particular, we show that under certain mild restrictions the data complexity of query answering remains in AC$^0$, i.e., as in the usual, nontemporal case. On the practical side, TQL is tailored specifically to offer maximum expressivity while preserving the possibility of reusing standard first-order rewriting techniques and tools for OWL 2 QL.

1 Introduction

Ontology-based data access (OBDA) is a popular paradigm of managing information, which combines the data storage and querying capabilities offered by relational database management systems (RDBMSs) with semantically enhanced view on the data provided by ontologies. OWL 2 QL is an OWL 2 profile, based on the DL-Lite family of Description Logics, designed specifically to support optimally balanced OBDA [6]. As large portions of data available through the Web are in fact still hosted in traditional relational datastores, OBDA provides a crucial channel for accessing this data from the level of the Semantic Web applications. With this work, we aim to establish an analogical to OBDA interface between the semantic layer of OWL 2 QL and temporal data stored and managed using SQL:2011, the most recent standardization of the SQL query language, which provides unprecedented support for validity time of data [11]. In this way we hope to define a convenient framework for reasoning with temporal semantic data — the problem gaining ever more attention within the Semantic Web community.

The temporal query language (TQL), which we propose for this task, is based on naturally characterizable combinations of temporal logic with conjunctive queries, identified in [10]. TQL is tailored specifically to offer maximum expressivity while preserving the possibility of reusing first-order rewriting techniques and tools, central to OBDA and developed specifically for the use with OWL 2 QL. While this technical compliance warrants the practicality of our approach, its well-defined logic foundations allow us to identify basic formal properties of TQL. In particular, we are able to demonstrate that under a mild restriction to finite time domains the data complexity of query answering remains in AC$^0$, i.e., as in the standard, nontemporal case. As the main result, we present a translation of TQL queries in the presence of OWL 2 QL ontologies to SQL:2011, which opens the way to efficient query answering by means of existing, commercially supported RDBMSs, such as IBM DB2 10.1, Oracle Database 11g Workspace Manager, or Teradata — all having adopted by now certain variants of the SQL:2011 standard.

---

1See http://www.cs.arizona.edu/~rts/sql3.html for an overview.
Preliminaries

We start by recapping the foundations of OBDA and temporal data. Next, we motivate our research problem with an illustrative application scenario.

2.1 Ontology-based data access

OWL 2 QL is a profile of OWL 2 Web Ontology Language, based on the DL-Lite family of Description Logics (DLs) [6]. A DL vocabulary $\Sigma = (N_I, N_C, N_R)$ consists of countably infinite sets of individual names ($N_I$), concept names ($N_C$) and role names ($N_R$). The ABox $A$ is a finite set of assertions $A(a)$ and $r(a, b)$, for $a, b \in N_I$, $A \in N_C$ and $r \in N_R$. The TBox $T$ is a finite set of concept and role inclusions $B \sqsubseteq C$, $r \sqsubseteq s$, built using logical constructors allowed in OWL 2 QL. The semantics is given in terms of DL interpretations $I = (\Delta_I, I)$, defined as usual [3]. An interpretation $I$ is a model of $T$ and $A$, denoted as $I \models T, A$, iff it satisfies every axiom in $T$ and $A$.

In OBDA, the instance data, represented as an ABox, is accessed via an ontology, given as a TBox, using a designated query language, such as most commonly considered in that context, the language of conjunctive queries [9]. Let $N_V$ be a countably infinite set of variables. A conjunctive query (CQ) over a DL vocabulary $\Sigma$ is a first-order formula $\exists \vec{u}, \vec{v} \phi(\vec{x}, \vec{y})$, where $\vec{x}, \vec{y}$ are sequences of variables. The sequence $\vec{x}$ denotes the free (individual) variables in the query, while $\vec{y}$ the quantified ones. The formula $\phi$ is a conjunction of atoms over $\Sigma$ of the form $A(u), r(u, v)$, where $u, v \in N_V \cup N_I$ are called terms. By $\text{term}(q)$ we denote the set of all terms occurring in a CQ $q$ and by $\text{obj}(q)$ the set of all its free variables. We call $q$ grounded whenever $\text{obj}(q) = \emptyset$. A grounded CQ $q$ is satisfied in $I$ iff there exists a mapping $\mu : \text{term}(q) \rightarrow \Delta_I$, with $\mu(a) = a^x$ for every $a \in N_I$, such that $\mu(u) \in A^x$ and $r(u, v) \in r^x$ for every $A(u)$ and $r(u, v)$ in $q$. Further, we say that $q$ is entailed by $T, A$, denoted as $T, A \models q$ iff $q$ is satisfied in every model of $T, A$. Whenever $\emptyset, A \models q$ we also write $A \models q$. An answer to $q$ is a mapping $\sigma : \text{obj}(q) \rightarrow N_I$. By $Q_\Sigma$ we denote the class of all CQs over the vocabulary $\Sigma$.

A prominent property of CQs is their first-order (FO) rewritability in OWL 2 QL.

**Definition 1** (FO rewritability [6]). For every CQ $q \in Q_\Sigma$ and a TBox $T$, there exists a FO formula $q^T$, called the FO rewriting of $q$ in $T$, such that for every ABox $A$ and answer $\sigma$ to $q$, it holds that:

$$T, A \models \sigma(q) \text{ iff } db(A) \models \sigma(q^T),$$

where $\models$ is the FO satisfaction relation and $db(A)$ denotes $A$ considered as a database/FO interpretation, i.e., a structure $(N_I, I^D)$, where $N_I$ serves as the interpretation domain and $I^D$ is an interpretation function, defined as:

- $A^D = \{a \in N_I \mid A(a) \in A\}$, for every $A \in N_C$,
- $r^D = \{(a, b) \in N_I \times N_I \mid r(a, b) \in A\}$, for every $r \in N_R$.

---

2See http://www.w3.org/TR/owl2-profiles/#OWL_2_QL for full details.
FO rewritability is particularly significant from the practical perspective. It implies that answering CQs in OWL 2 QL can be effectively performed in existing RDBMSs via a translation to SQL, as the ontological component can be always compiled out in the query rewriting, without loss of soundness or completeness. As a theoretical corollary, it follows also that the data complexity of CQ answering in this setup is \( \mathcal{AC}^0 \), as in the first-order logic (FOL).

In what follows, we focus exclusively on OWL 2 QL TBoxes, even though some of the presented results should clearly transfer to other fragments of DLs enjoying FO rewritability. We hence implicitly assume that every TBox or ontology mentioned in the remainder of this report is expressed in OWL 2 QL.

2.2 Temporal databases

SQL:2011 takes a minimal, regulative approach to extending the relational data model with the temporal dimension [11]. It accounts for two extra columns included in database’s tables, designed for storing the beginning and the end time of the validity periods of respective records. Formally, such time-stamping mechanism is based on intervals over linear time domains.

**Definition 2 (Time domain, time intervals).** A time domain is a tuple \( \mathfrak{T} = (T, <) \), where \( T \) is a nonempty set of elements called time points and \(<\) is an irreflexive, linear ordering on \( T \). A time interval \( \tau = [\tau^-, \tau^+] \) over \( \mathfrak{T} \) is a set of time points \( \{t \in T \mid \tau^- \leq t \leq \tau^+\} \), where \( \tau^-, \tau^+ \in T \), such that \( \tau^- \leq \tau^+ \), are called the beginning and the end of \( \tau \). The set of all time intervals over \( \mathfrak{T} \) is denoted by \( I \).

Effectively, SQL:2011 provides direct support for the representation of what is traditionally known as concrete temporal databases, i.e., finite syntactic encodings of temporal data. The actual meaning of these encodings is captured by possibly infinite abstract temporal databases [8]. In the OBDA setting these two notions translate naturally into two types of ABoxes.

**Definition 3 (Concrete and abstract temporal ABoxes).** A temporal assertion is an expression \( \tau : \alpha \), where \( \alpha \) is an ABox assertion and \( \tau \in I \), stating that \( \alpha \) is valid in every time point in \( \tau \). A concrete temporal ABox (CTA) \( \mathfrak{A} \) is a finite set of temporal assertions. For a concrete temporal ABox \( \mathfrak{A} \) its corresponding abstract temporal ABox (ATA) is a sequence \( (\mathfrak{A}_t)_{t \in T} \), where \( \mathfrak{A}_t = \{\alpha \mid \tau : \alpha \in \mathfrak{A} \text{ and } t \in \tau\} \).

On the query level, SQL:2011 introduces a collection of predefined, binary, interval predicates to be used in the WHERE clauses of SQL queries for comparing pairs of time periods, e.g.: CONTAINS(\( \tau_1, \tau_2 \)), OVERLAPS(\( \tau_1, \tau_2 \)), PRECEDES(\( \tau_1, \tau_2 \)), etc.

2.3 Ontology-based access to temporal data

We study ontology-based access to temporal data in the sense of an extension to the OBDA paradigm whose prototypical application could be illustrated with the following scenario.

Consider the SQL:2011 database presented in Table 1, with columns \texttt{from} and \texttt{to} marking the limits of the validity periods of the records. Such databases can be straightforwardly restated as temporal ABoxes, by applying the usual mapping from relational data to DLs [6], accompanied with an obvious mapping for handling time-stamps. Table 2 contains temporal ABoxes representing the data from the first record of the table \texttt{Emp}, for \( T = \mathbb{N} \). We further envision a language for querying such temporal ABoxes, which combines support for two essential functionalities: representation of temporal constraints over the validity periods of data and semantically enhanced access to that data via ontologies. For instance, given the ontology
Table 1: SQL:2011 temporal database.

</tbody>
</table>

Table 2: Temporal ABoxes: a CTA (left) and an ATA (right).

\[
\begin{array}{|c|}
\hline
A_{[1998,2000]} : Emp(e1) \\
A_{[1998,2000]} : name(e1,john) \\
A_{[1998,2000]} : department(e1,d1) \\
\hline
\end{array}
\]

\[
\begin{array}{|c|c|c|c|}
\hline
\mathcal{T} = \{ Emp \sqsubseteq Person, department \sqsubseteq worksAt, location \sqsubseteq basedIn\} \text{, the language should be able to support queries such as:} \\
\end{array}
\]

\[
(Q) \text{ Find all persons } x \text{ and periods } y, \text{ such that } x \text{ worked in a department based in Barcelona during } y, \text{ but earlier } x \text{ worked in a department based in Madrid.}
\]

The expected answers should then include \( \{ x \mapsto e1, y \mapsto [1999,2000] \} \). The practical rationale behind thus defined ontology-based access to temporal data is to eventually enable such queries to be translated to SQL:2011 and answered within existing RDBMSs.

3 Temporal Query Language

The language TQL, presented in this section, is defined using a generic construction method for temporal query languages in DLs, explored in [10, 3, 5]. TQL is a combination of a temporal language with CQs, obtained by substituting CQs for the atoms in temporal formulas. This design allows for very flexible interleaving of data queries with temporal constraints, while benefiting from the expressive power of both components. Here we use an interval-based variant of the temporal component, rather than a point-based, which facilitates direct querying of concrete databases, without requiring intermediate translations. The CQs are embedded in the temporal language using the epistemic semantics. This approach, suggested in [10], makes our proposal practical in the sense of immediately warranting the desirable rewritability properties of the resulting temporal queries.

As the first step, we compile out a part of the temporal component of TQL into custom interval predicates, interpreted here as predicates expressible in a simple algebra over time points. Note that on linear orders \( u \leq v \) is definable as \( \neg (v < u) \), while \( v = u \) as \( u \leq v \land v \leq u \).

**Definition 4 (Interval predicates).** An \( n \)-ary interval predicate \( \omega(\tau_1, \ldots, \tau_n) \) is given by its name \( \omega \) and the defining condition expressed as a formula \( \varpi \) in the language:

\[
\varpi := u < v \mid \neg \varpi \mid \varpi_1 \land \varpi_2
\]

where \( u, v \in \{ \tau_i^-, \tau_i^+ \mid 1 \leq i \leq n \} \). For a time domain \( \Sigma = (T, <) \) and any \( \tau_1, \ldots, \tau_n \in I \), a predicate \( \omega(\tau_1, \ldots, \tau_n) \) evaluates to True whenever \( \varpi(\tau_1, \ldots, \tau_n) \) is satisfied in \( \Sigma \) and to False.
otherwise, where $<$ is interpreted as the ordering in $\Sigma$ and $\neg, \land$ as usual. The set of all interval predicates is denoted by $\Omega$.

Next, we incorporate interval predicates in the temporal query language. By $I_V$ we denote a countably infinite set of variables ranging over $I$.

**Definition 5 (TQL).** Temporal query language (TQL) is the smallest set of formulas constructed according to the grammar:

$$
\psi ::= [q(u) \mid \omega(u_1, \ldots, u_n) \mid \neg \psi \mid \psi_1 \land \psi_2 \mid \exists y. \psi
$$

where $u, u_1, \ldots, u_n \in I \cup I_V$, $y \in I_V$, $q \in Q_\Sigma$, and $\omega \in \Omega$. An $I$-substitution is a mapping $\pi : I \cup I_V \to I$ such that $\pi(\tau) = \tau$ for every $\tau \in I$. By $\text{obj} (\psi)$ we denote the set of free individual variables and by $\text{int} (\psi)$ the set of free interval variables in $\psi$. A TQL formula $\psi$ is grounded iff $\text{obj} (\psi) = \text{int} (\psi) = \emptyset$. The satisfaction relation for grounded TQL formulas, w.r.t. a TBox $T$, a CTA $A$, and an $I$-substitution $\pi$, is defined inductively as follows:

$$
\begin{align*}
(\dagger) & \quad T, A, \pi \models [q](u) \quad \text{iff} \quad T, A_i \models q, \text{for every } t \in \pi(u), \\
T, A, \pi \models \omega(u_1, \ldots, u_n) & \quad \text{iff} \quad \omega(\pi(u_1), \ldots, \pi(u_n)), \\
T, A, \pi \models \neg \psi & \quad \text{iff} \quad T, A, \pi \not\models \psi, \\
T, A, \pi \models \psi_1 \land \psi_2 & \quad \text{iff} \quad T, A, \pi \models \psi_1 \text{ and } T, A, \pi \models \psi_2, \\
T, A, \pi \models \exists y. \psi & \quad \text{iff} \quad \text{there exists } \tau \in I, \text{ such that } T, A, \pi [y \mapsto \tau] \models \psi,
\end{align*}
$$

where $\pi[y \mapsto \tau]$ denotes the $I$-substitution exactly as $\pi$ except for that we fix $\pi(y) = \tau$. We say that $T, A$ entail a grounded TQL formula $\psi$, denoted as $T, A \models \psi$, iff there exists an $I$-substitution $\pi$, such that $T, A, \pi \models \psi$.

TQL formulas with free variables can naturally serve as queries over concrete temporal ABoxes. We refer to such formulas as concrete TQL queries (CTQs). As an example of a CTQ, consider a rephrasing of the query (Q) from Section 2.3:

$$
\psi(x, y) := [\exists z. (\text{Person}(x) \land \text{worksAt}(x, z) \land \text{basedIn}(z, \text{barcelona}))[y] \land
\exists v. (\text{PRECEDES}(v, y) \land [\exists z. (\text{worksAt}(x, z) \land \text{basedIn}(z, \text{madrid}))[v])
$$

where the meaning of $\text{PRECEDES}$ is as expected. As one of its answers, $\psi(x, y)$ should return $\{x \mapsto e1, y \mapsto [1999, 2000]\}$, which is a compact representation of all answers to this query over the temporal database in Section 2.3.

Finally, we define the certain answer semantics for TQL queries.

**Definition 6 (CTQ answering).** Let $T$ be a TBox, $A$ a CTA and $\psi$ a CTQ with free variables $\text{obj}(\psi)$ and $\text{int}(\psi)$. An answer to $\psi$ is a mapping $\sigma$ such that $\sigma : \text{obj}(\psi) \mapsto N_t$ and $\sigma : \text{int}(\psi) \mapsto I$. By $\sigma(\psi)$ we denote the result of uniformly substituting every occurrence of $x$ in $\psi$ with $\sigma(x)$, for every $x \in \text{obj}(\psi) \cup \text{int}(\psi)$. An answer $\sigma$ is called certain over $T, A$ iff $T, A \models \sigma(\psi)$.

### 4 Query rewriting

The key to the formal design of TQL is condition $(\dagger)$, in Definition 5, which ensures the epistemic interpretation of the CQs embedded in TQL queries. The formula $[q](\tau)$, for a grounded $q \in Q_\Sigma$ and $\tau \in I$, reads as “$q$ is entailed in all time points in $\tau$”. Analogically, $\neg[q]$ is interpreted as negation-as-failure: “it is not true that $q$ is entailed in all time points in $\tau$”. As a consequence,
condition (†) can be effectively replaced with its equivalent, which involves the standard FO rewritability techniques in the sense of Definition 1:

\[ T, \mathcal{A}, \pi \models [q](u) \iff db(\mathcal{A}_t) \models q^T, \text{ for every } t \in \pi(u), \]

where \( q^T \) is an FO rewriting of \( q \) in \( T \). What it eventually means, is that all occurrences of CQs in a CTQ can be replaced with their FO rewritings, so that the ontology \( T \) can be dropped, while the resulting formula can be evaluated exclusively over the temporal ABox seen as a sequence of FO interpretations. In what follows, we make this observation formally precise. Essentially, we rewrite CTQs into a special temporal FO form, and show that such rewritings preserve the correctness of query answering. Importantly, the FO component in the rewritings is defined purely in terms of the standard FO rewritings of the respective CQs. To ease the proof of the subsequent complexity result, the temporal component is moreover rephrased from an interval- to point-based.

**Definition 7 (TFO rewriting of CTQs).** A temporal FO rewriting of a CTQ \( \psi \) is a formula \([\psi]_{TFO}\) obtained from \( \psi \) by applying the transformation \([\cdot]_{TFO}\), defined inductively as follows:

- \([q](u)]_{TFO} = \forall x.(u^- \leq x \leq u^+ \rightarrow (q^T)(x))\]
- \([\omega(\bar{u})]_{TFO} = \bar{\omega}(\bar{u})\]
- \([\neg \psi]_{TFO} = \neg[\psi]_{TFO}\]
- \([\psi_1 \land \psi_2]_{TFO} = [\psi_1]_{TFO} \land [\psi_2]_{TFO}\]
- \([\exists y.\psi]_{TFO} = \exists y^-.y^+.y^-. \leq y^+ \land [\psi]_{TFO}\]

By \( \text{obj}([\psi]_{TFO}) \) we denote the set of free individual variables and by \( \text{pt}([\psi]_{TFO}) \) the set of free point variables in \([\psi]_{TFO}\). For every answer \( \sigma \) to \( \psi \), we define the corresponding answer \( \sigma^* \) to \([\psi]_{TFO}\), such that \( \sigma^* : \text{obj}([\psi]_{TFO}) \mapsto \mathbb{N}_1 \) and \( \sigma^* : \text{pt}([\psi]_{TFO}) \mapsto T \), where:

- \( \sigma^*(x) := \sigma(x) \), for every \( x \in \text{obj}(\psi) \),
- \( \sigma^*(x^-) := \sigma(x^-) \) and \( \sigma^*(x^+) := \sigma(x^+) \), for every \( x \in \text{int}(\psi) \).

As usually, we assume that \( \forall x.\phi = \neg \exists x.\neg \phi \) and \( \phi_1 \rightarrow \phi_2 = \neg(\phi_1 \land \neg \phi_2) \). Note that whenever \( x \in \text{lv} \) then \( x^- \), \( x^+ \in \text{T} \) are two variables uniquely associated with \( x \). Consequently, given the transformation rules, there exists a one-to-one correspondence between answers to CTQs and to their TFO rewritings.

The semantics of the rewriting \([\psi]_{TFO}\) is defined over a sequence of databases/FO interpretations \((db(\mathcal{A}_t))_{t \in T})\), based on the CTA \( \mathcal{A} \), where every \( db(\mathcal{A}_t) \) is specified as in Definition 1.

**Definition 8 (TFO semantics).** A T-substitution is a mapping \( \pi : T \cup \text{T} \rightarrow T \) such that \( \pi(t) = t \) for every \( t \in T \). Whenever \( \text{obj}([\psi]_{TFO}) = \text{pt}([\psi]_{TFO}) = \emptyset \) the satisfaction relation for \([\psi]_{TFO}\), w.r.t. a T-substitution \( \pi \), is defined inductively as follows:

- \((db(\mathcal{A}_t))_{t \in T}, \pi \models (q^T)(u) \) if \( db(\mathcal{A}_{\pi(u)}) \models q^T \),
- \((db(\mathcal{A}_t))_{t \in T}, \pi \models u < v \) if \( \pi(u) < \pi(v) \),
- \((db(\mathcal{A}_t))_{t \in T}, \pi \models \neg \phi \) if \( (db(\mathcal{A}_t))_{t \in T}, \pi \models \neg \phi \),
- \((db(\mathcal{A}_t))_{t \in T}, \pi \models \phi_1 \land \phi_2 \) if \( (db(\mathcal{A}_t))_{t \in T}, \pi \models \phi_1 \) and \( (db(\mathcal{A}_t))_{t \in T}, \pi \models \phi_2 \),
- \((db(\mathcal{A}_t))_{t \in T}, \pi \models \exists y.\phi \) if there exists \( t \in T \), such that \( (db(\mathcal{A}_t))_{t \in T}, \pi[y \mapsto t] \models \phi \).
where $\pi[y \mapsto t]$ denotes the $T$-substitution exactly as $\pi$ except for that we fix $\pi(y) = t$. We say that a grounded TFO formula $[\psi]^{TFO}$ is satisfied in $(db(T))_{t \in T}$, denoted as $(db(T))_{t \in T} \models [\psi]^{TFO}$, iff there exists a $T$-substitution $\pi$, such that $(db(T))_{t \in T}, \pi \models [\psi]^{TFO}$.

The following theorem ensures the correctness of query answering under the TFO rewriting. The proof, included in Appendix, follows by structural induction over the syntax of CTQs and their rewritings.

**Theorem 1** (Correctness of TFO rewriting). Let $\psi$ be a CTQ and $T$ a TBox. Then for every answer $\sigma$ to $\psi$ and CTA $\mathfrak{A}$ it holds that:

$$T, \mathfrak{A} \models \sigma(\psi) \text{ iff } (db(\mathfrak{A}))_{t \in T} \models \sigma^*([\psi]^{TFO}).$$

Given some further shallow refinements to the resulting TFO form, TQL can be easily seen as a fragment of two-sorted FOL, or alternatively, as a fragment of First-Order Temporal Logic [12]. Both types of languages have been studied in the context of temporal databases [7]. The data complexity of query answering in such formalisms depends strongly on the choice of the underlying time domain and can range from $AC^0$ to undecidable. A natural strategy to ensure the desirable $AC^0$ complexity is to restrict time domains to finite ones only. This result, presented in Theorem 2, follows by the correspondence of TQL to yet another known formalism: FOL with restricted arithmetic [13].

**Theorem 2** (Complexity). The data complexity of answering CTQs in the presence of TBoxes, and over finite time domains $\Sigma = (T, <)$ is in $AC^0$.

Under the finite time domain assumption, the resulting TFO queries can be effectively translated into SQL:2011 and evaluated using existing RDBMSs with SQL:2011 support. This final translation, and its efficient generation by means of existing CQ rewriting tools, is the ultimate goal of the studied scenario, and remains part of our future research agenda.

## 5 Related work

Part of work related to this research comes from the field of temporal databases [7] [8]. Although providing some theoretical grounding for our proposal, these contributions are obviously agnostic about the ontology-based approach on the problem, which we concentrate on here.

The research on temporal extensions to OBDA has been taken up only very recently by Borgwardt et al. [3] [5] and Artale et al. [2]. In [3], the authors study the same prototypical scenario as addressed here, but focus on its more foundational aspects. They consider a more expressive DL $ALC$ as the background ontology language and adopt a less restrictive definition of temporal queries. This offers a richer setting, yet without apparent application prospects in the context of existing temporal databases. The work in [5] is closer aligned with ours. It considers DL-$Lite$ ontologies and studies a rewriting approach based on the use of standard CQ rewriting techniques. It remains complementary to the present contribution in that it employs a somewhat different query language (no epistemic interpretation of embedded CQs, no negation), and does not focus on the task of querying temporal data via SQL:2011, which is the guiding motive for our work. In [2], the authors pursue an alternative approach to temporal OBDA. Instead of adding temporal features to query languages, they focus on defining suitable temporal extensions to OWL 2 QL, in the spirit of known temporal DLs [1]. The practical implications of this work have not been yet investigated.
6 Conclusions

We propose a practical approach to lifting the popular paradigm of OBDA to temporal case. The presented language TQL allows for querying temporal data stored in relational databases via a semantic layer of OWL 2 QL ontologies. We believe that this proposal, to be further developed in future research, strikes a good balance between the theoretical strength of its formal foundations and the feasibility of practical applications, warranted by the possibility of answering TQL queries in commercially supported RDBMSs via a translation to SQL:2011.

From a more general perspective, considering the growing interest in temporal extensions of OBDA, it is critical to continue the formal study of temporal features supported by the SQL standards, temporal extensions to logic-based query languages and ontology languages intended for use in practical OBDA scenarios, and finally, the relationships holding between all of them. In this respect, it is highly desirable to establish stronger links between the approach pursued here and those proposed recently in [3, 5, 2], with the prospect of gaining a clearer view on the landscape of technical possibilities regarding the temporal OBDA.

References

Appendix

Proof of Theorem 1. As remarked under Definition 2 there exists a one-to-one correspondence between answers to CTQs and to their TFO rewritings, simply because every free interval variable is replaced with a pair of time point variables, binding over the beginning and the end of the interval. We can further identify a similar correspondence between $I$- and $T$-substitutions for the respective formulas. For an $I$-substitution $\pi$ we define $T$-substitution $\pi^t$, by fixing:
$$\pi^t(u^-) := \pi(u^-) \text{ and } \pi^t(u^+) := \pi(u^+), \text{ for every } u \in I \cup \mathbb{V}.$$

Note, however, that TFO rewritings might contain extra variables added in the transformation of expressions $[q](u)$ into $\forall x.(u^- \leq x \leq u^+ \rightarrow (q^T)(x))$. Consequently, an $I$-substitution $\pi$ can be uniquely associated with a set of $T$-substitutions $\pi^t$, differing with the assignment of every such variable $x$, which is set as $\pi^t(x) := t$, for some $\pi^t(u^-) \leq \pi^t(u^+)$.

Based on these correspondences, we show that for every pair of answers $\sigma$ and $\sigma^*$ to a CTQ and its TFO rewriting, the former formula is satisfied iff the latter is, under the respective semantics, w.r.t. corresponding substitutions.

($\Rightarrow$) Let $\psi$ be a CTQ and $T, A \models \sigma(\psi)$, for some $\sigma, T$ and $A$. We show that $(db(A_i))_{i \in T} \models \sigma^t([\psi]^{TFO})$. For simplicity, we assume that $\psi$ and $[\psi]^{TFO}$ are already grounded with the respective answers. By Definition 6, there must exist an $I$-substitution $\pi$, such that $T, A, \pi \models \psi$. We proceed by structural induction to show that $(db(A_i))_{i \in T}, \pi^t \models [\psi]^{TFO}$. The first case is the critical one. Suppose $T, A, \pi \models [q](u)$, and therefore, that $T, A, \pi \models q$, for every $t \in \pi(u)$. Then it should hold that $(db(A_i))_{i \in T}, \pi^t \models \forall x.(u^- \leq x \leq u^+ \rightarrow (q^T)(x))$. But this follows immediately by the semantics of $[\psi]^{TFO}$, definition of $\pi^t$, and the FO rewritability of CQs (Definition 1). Observe that for $\pi^t(x) = t \in \pi(u)$ it is indeed the case that $(db(A_i))_{i \in T}, \pi^t \models u^- \leq x \leq u^+ \rightarrow q^T$, as clearly $T, A, \pi \models q$. For $T, A, \pi \models \omega(u_1, \ldots, u_n)$, the satisfaction of $\omega(u)$ is immediate by the semantics of TQL. The cases of $\neg, \land$ are straightforward. For $\exists y, \psi$, observe that whenever there exists $\tau \in I$, such that $T, A, \pi \models y \rightarrow \tau \models \psi$, then there must also exist $\tau^- \land \tau^+ \in T$, such that $\tau^- \leq \tau^+$ and $(db(A_i))_{i \in T}, \pi \models \tau^- \land \tau^+ \models \phi$.

($\Leftarrow$) This direction follows by the inverse argument to the above, and rests on the same correspondences between $T$- and $I$-substitutions.

Proof of Theorem 2. We observe that the language of TFO rewritings of CTQs can be also seen as FOL with restricted arithmetic, where $T$ represents a set of numbers and $< \leq$ the less-than predicate. To emphasize that view we slightly revise the syntax of the CTAs and the TFO rewritings, and internalize the temporal argument into all predicates. We define $\mathcal{A}^{\mathbb{N}} = \bigcup_{i \in T} \mathcal{A}^{\mathbb{N}_i}$, where $\mathcal{A}^{\mathbb{N}_i} = \{ A(a, t) \mid A(a) \in \mathcal{A}_i \} \cup \{ r(a, b, t) \mid r(a, b) \in \mathcal{A}_i \}$. Then by $db(\mathcal{A}^{\mathbb{N}})$ we denote $\mathcal{A}^{\mathbb{N}}$ considered as a database/FO interpretation, analogically as specified in Definition 1. Further, we write $q^T(x)^{\mathbb{N}} = \bigcup_i q_i(x)^{\mathbb{N}_i}$, where $q_i^T = \bigcup_i q_i$ and $q_i(x)^{\mathbb{N}}$ is obtained from $q_i$, by replacing every atom $A(u)$ and $r(u, v)$ in $q_i$ with $A(u, x)$ and $r(u, v, x)$ respectively. The first TFO transformation rule is revised to:
$$[q](u)^{TFO} = \forall x.(u^- \leq x \leq u^+ \rightarrow (q^T(x)^{\mathbb{N}}),$$

The FO rewriting is interpreted over $\mathcal{A}^{\mathbb{N}}$ via the standard FO satisfaction relation. In particular $q^T(x)^{\mathbb{N}}$ is interpreted as $\mathcal{A}^{\mathbb{N}} \models q^T(x)^{\mathbb{N}}$.

The data complexity of FOL with arithmetic $(\mathbb{N}, <)$, where $\mathbb{N} \subseteq \mathbb{N}$ is a finite initial segment of natural numbers $\mathbb{N}$, is known to be $\text{AC}^0$ [13]. Clearly, every finite time domain $\mathcal{T} = (T, <)$ can be isomorphically mapped to the initial segment $\{0, 1, \ldots, |T| - 1\}$ of $\mathbb{N}$. Therefore, query answering in TQL over such domains corresponds to query answering in FOL with $(\mathbb{N}, <)$, and must belong, as a consequence, to the same complexity class.
