Abstract

In this paper, we introduce methods of encoding propositional logic programs in vector spaces. Interpretations are represented by vectors and programs are represented by matrices. The least model of a definite program is computed by multiplying an interpretation vector and a program matrix. To optimize computation in vector spaces, we provide a method of partial evaluation of programs using linear algebra. Partial evaluation is done by unfolding rules in a program, and it is realized in a vector space by multiplying program matrices. We perform experiments using randomly generated programs and show that partial evaluation has potential for realizing efficient computation in huge scale of programs.

1 Introduction

One of the challenging topics in AI is to reason with huge scale of knowledge bases. Linear algebraic computation has potential to make symbolic reasoning scalable to real-life datasets, and several studies aim at integrating linear algebraic computation and symbolic computation. For instance, Grefenstette (2013) introduces tensor-based predicate calculus that realizes logical operations. Yang, et al. (2015) introduce a method of mining Horn clauses from relational facts represented in a vector space. Serafini and Garcez (2016) introduce logic tensor networks that integrate logical deductive reasoning and data-driven relational learning. Sato (2017a) formalizes Tarskian semantics of first-order logic in vector spaces, and (Sato 2017b) shows that tensorization realizes efficient computation of Datalog. Lin (2013) introduces linear algebraic computation of SAT for clausal theories.

To realize linear algebraic computation of logic programming, Sakama et al. (2017) introduce encodings of Horn, disjunctive and normal logic programs in vector spaces. They show that least models of Horn programs, minimal models of disjunctive programs, and stable models of normal programs are computed by algebraic manipulation of third-order tensors. The study builds a new theory of logic programming, while implementation and evaluation are left open.
In this paper, we first reformulate the framework of (Sakama et al. 2017) and present an algorithm for computing least models of definite programs in vector spaces. We next introduce two optimization techniques for computing: the first one is based on column reduction of matrices, and the second one is based on partial evaluation. We perform experimental testing and compare algorithms for computing fixpoints of definite programs. The rest of this paper is organized as follows. Section 2 reviews basic notions and Section 3 provides linear algebraic characterization of logic programming. Section 4 presents partial evaluation of logic programs in vector spaces. Section 5 provides experimental results and Section 6 summarizes the paper. Due to space limit, we omit proofs of propositions and theorems.

2 Preliminaries

We consider a language $\mathcal{L}$ that contains a finite set of propositional variables. Given a logic program $P$, the set of all propositional variables appearing in $P$ is called the Herbrand base of $P$ (written $BP$). A definite program is a finite set of rules of the form:

$$h \leftarrow b_1 \land \cdots \land b_m \quad (m \geq 0)$$

where $h$ and $b_i$ are propositional variables in $\mathcal{L}$. A rule is called a d-rule if $r$ is the form:

$$h \leftarrow b_1 \lor \cdots \lor b_m \quad (m \geq 0)$$

where $h$ and $b_i$ are propositional variables in $\mathcal{L}$. A d-program is a finite set of rules that are either (1) or (2). Note that the rule (2) is a shorthand of $m$ rules: $h \leftarrow b_1, \ldots, h \leftarrow b_m$, so a d-program is considered a definite program.\footnote{The notion of d-programs is useful when we consider a program such that each atom is defined by a single rule in Section 3.} For each rule of the form (1) or (2), define $\text{head}(r) = h$ and $\text{body}(r) = \{b_1, \ldots, b_m\}$.\footnote{We assume $b_i \neq b_j$ if $i \neq j$.}

A set $I \subseteq BP$ is an interpretation of $P$. An interpretation $I$ is a model of a d-program $P$ if $\{b_1, \ldots, b_m\} \subseteq I$ implies $h \in I$ for every rule (1) in $P$, and $\{b_1, \ldots, b_m\} \cap I \neq \emptyset$ implies $h \in I$ for every rule (2) in $P$. A model $I$ is the least model of $P$ if $I \subseteq J$ for any model $J$ of $P$. A mapping $TP : 2^{BP} \rightarrow 2^{BP}$ (called a $TP$-operator) is defined as:

$$TP(I) = \{ h \mid h \leftarrow b_1 \land \cdots \land b_m \in P \text{ and } \{b_1, \ldots, b_m\} \subseteq I \}$$

$$\cup \{ h \mid h \leftarrow b_1 \lor \cdots \lor b_m \in P \text{ and } \{b_1, \ldots, b_m\} \cap I \neq \emptyset \}.$$

The powers of $TP$ are defined as: $TP^{k+1}(I) = TP(TP^k(I))$ ($k \geq 0$) and $TP^0(I) = I$. Given $I \subseteq BP$, there is a fixpoint $TP^{n+1}(I) = TP^n(I)$ ($n \geq 0$). For a definite program $P$, the fixpoint $TP^n(\emptyset)$ coincides with the least model of $P$ (van Emde & Kowalski 1976).

3 Logic Programming in Linear Algebra

3.1 SD programs

We first consider a subclass of definite programs, called SD programs.
Definition 1 (SD program)
A definite program $P$ is called 
\textit{singly defined} (SD program, for short) if $\text{head}(r_1) \neq \text{head}(r_2)$ for any two rules $r_1$ and $r_2$ ($r_1 \neq r_2$) in $P$.

Interpretations and programs are represented in a vector space as follows.

Definition 2 (interpretation vector (Sakama et al. 2017))
Let $P$ be a definite program and $B_P = \{p_1, \ldots, p_n\}$. Then an interpretation $I \subseteq B_P$ is represented by a vector $v = (a_1, \ldots, a_n)^T$ where each element $a_i$ ($1 \leq i \leq n$) represents the truth value of the proposition $p_i$ such that $a_i = 1$ if $p_i \in I$; otherwise, $a_i = 0$. We write $\text{row}_I(v) = p_i$. Given $v = (a_1, \ldots, a_n)^T \in \mathbb{R}^n$, define $v[i] = a_i$ ($1 \leq i \leq n$) and $v[1\ldots k] = (a_1, \ldots, a_k)^T \in \mathbb{R}^k$ ($k \leq n$).

Definition 3 (matrix representation of SD programs)
Let $P$ be an SD program and $B_P = \{p_1, \ldots, p_n\}$. Then $P$ is represented by a matrix $M_P \in \mathbb{R}^{n \times n}$ such that for each element $a_{ij}$ ($1 \leq i, j \leq n$) in $M_P$,
\begin{enumerate}
  \item $a_{ij} = \frac{1}{m}$ (1 \leq k \leq m; 1 \leq i, j_k \leq n) if $p_i \leftarrow p_{j_1} \land \cdots \land p_{j_m}$ is in $P$;
  \item $a_{ii} = 1$ if $p_i \leftarrow$ is in $P$;
  \item $a_{ij} = 0$, otherwise.
\end{enumerate}

$M_P$ is called a \textit{program matrix}. We write $\text{row}_i(M_P) = p_i$ and $\text{col}_j(M_P) = p_j$ ($1 \leq i, j \leq n$).

In $M_P$, the $i$-th row corresponds to the atom $p_i$ appearing in the head of a rule, and the $j$-th column corresponds to the atom $p_j$ appearing in the body of a rule. On the other hand, every fact $p_i \leftarrow$ in $P$ is represented as a tautology $p_i \leftarrow p_i$ in $M_P$.

Example 1
Consider $P = \{p \leftarrow q, \: q \leftarrow p \land r, \: r \leftarrow s, \: s \leftarrow \}$ with $B_P = \{p, q, r, s\}$. Then $M_P$ becomes
\[
\begin{pmatrix}
0 & 1 & 0 & 0 \\
1/2 & 0 & 1/2 & 0 \\
0 & 0 & 0 & 1 \\
0 & 0 & 0 & 1
\end{pmatrix}
\]
where $\text{row}_1(M_P) = p$ and $\text{col}_2(M_P) = q$.

Definition 4 (initial vector)
Let $P$ be a definite program and $B_P = \{p_1, \ldots, p_n\}$. Then the \textit{initial vector} of $P$ is an interpretation vector $v_0 = (a_1, \ldots, a_n)^T$ such that $a_i = 1$ ($1 \leq i \leq n$) if $\text{row}_i(v_0) = p_i$ and a fact $p_i \leftarrow$ is in $P$; otherwise, $a_i = 0$.

Definition 5 ($\theta$-thresholding)
Given a vector $v = (a_1, \ldots, a_n)^T$, define $\theta(v) = (a'_1, \ldots, a'_n)^T$ where $a'_i = 1$ ($1 \leq i \leq n$) if $a_i \geq 1$; otherwise, $a'_i = 0$.\footnote{\textit{a}$_i$ can be greater than 1 only later when d-rules come into play.} We call $\theta(v)$ the \textit{$\theta$-thresholding} of $v$.

Given a program matrix $M_P \in \mathbb{R}^{n \times n}$ and an initial vector $v_0 \in \mathbb{R}^n$, define
\[
v_1 = \theta(M_P v_0) \quad \text{and} \quad v_{k+1} = \theta(M_P v_k) \quad (k \geq 1)
\]
It is shown that $v_{k+1} = v_k$ for some $k \geq 1$. When $v_{k+1} = v_k$, we write $v_k = \text{FP}(M_P v_0)$.
Theorem 1
Let $P$ be an SD program and $M_P \in \mathbb{R}^{n \times n}$ its program matrix. Then $m \in \mathbb{R}^n$ is a vector representing the least model of $P$ iff $m = FP(M_Pv_0)$ where $v_0$ is the initial vector of $P$.

Example 2
Consider the program $P$ of Example 1 and its program matrix $M_P$. The initial vector of $P$ is $v_0 = (0, 0, 0, 1)^T$. Then

$$M_Pv_0 = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 1/2 & 0 & 1/2 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} 0 \\ 0 \\ 0 \\ 1 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 1 \\ 1 \end{pmatrix}$$

and $v_1 = \theta(M_Pv_0) = (0, 0, 1, 1)^T$. Next,

$$M_Pv_1 = \begin{pmatrix} 1/2 & 0 & 1/2 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} 0 \\ 0 \\ 1 \\ 1 \end{pmatrix} = \begin{pmatrix} 1 \\ 1 \end{pmatrix}$$

and $v_2 = \theta(M_Pv_1) = v_1$. Hence, $v_2 = (0, 0, 1, 1)^T$ represents the least model $\{r, s\}$ of $P$.

Remark: The current study is different from the previous work (Sakama et al. 2017) in matrix representation of programs as follows.

- In (Sakama et al. 2017) a fact is represented as a rule “$p_i \leftarrow \top$” and is encoded in a matrix by $a_{ij} = 1$ where row$(M_P) = p_i$ and col$(M_P) = \top$. Different from the current study, the previous study sets the empty set as the initial vector and computes fixpoints. In this study, we start with the initial vector representing facts, instead of representing facts as rules in $M_P$. This has the effect of increasing zero elements in matrices and reducing the number of required iterations in fixpoint computation. Representing matrices in sparse forms also brings storage advantages with a good matrix library.
- In (Sakama et al. 2017) a constraint is represented as a rule “$\bot \leftarrow p_{j_1} \land \cdots \land p_{j_m}$” and is encoded in a matrix by $a_{ij} = \frac{1}{m}$ (1 ≤ $i$ ≤ $m$) where row$(M_P) = \bot$ and col$(M_P) = p_{j_i}$. In the current study, we do not include constraints in a program as it causes a problem in partial evaluation. Still, we can handle constraints separately from a program as follows. Given a program $P$ and constraints $C$, encode them by matrices $M_P \in \mathbb{R}^{n \times n}$ and $M_C \in \mathbb{R}^{(n+1) \times n}$, respectively, where $M_C$ has the element $\bot$ in its row. After computing the fixpoint $v_k = FP(M_Pv_0) \in \mathbb{R}^n$ as in Theorem 1, compute $M_Cv_k \in \mathbb{R}^{n+1}$. If row$(v_k) = \bot$ and $v_k[i] = a_i = 1$, then $P \cup C$ is inconsistent; otherwise, $v_k$ represents the least model of $P \cup C$.

3.2 Non-SD programs

When a definite program $P$ contains two rules: $r_1 : h \leftarrow b_1 \land \cdots \land b_m$ and $r_2 : h \leftarrow b_1 \land \cdots \land b_m$. $P$ is transformed to a d-program $P^\delta = (P \setminus \{r_1, r_2\}) \cup \{r'_1, r_2, d_1\}$ where $r'_1 : h_1 \leftarrow b_1 \land \cdots \land b_m$, $r'_2 : h_2 \leftarrow b_1 \land \cdots \land b_m$, and $d_1 : h \leftarrow h_1 \lor h_2$. Here, $h_1$ and $h_2$ are new propositional variables associated with $r_1$ and $r_2$, respectively.

Generally, a non-SD program is transformed to a d-program as follows.
Definition 6 (transformation)

Let $P$ be a definite program and $B_P$ its Herbrand base. For each $p \in B_P$, put $P_p = \{ r \mid r \in P \text{ and } \text{head}(r) = p \}$ and $R_P = \{ r \mid r \in P_p \text{ and } |P_p| > 1 \}$. Then define $S_p = \{ p_i \leftarrow \text{body}(r) \mid r \in R_P \text{ and } i = 1, \ldots, k \text{ where } k = |R_P| \}$ and $D_p = \{ p \leftarrow p_1 \lor \cdots \lor p_k \mid p_i \leftarrow \text{body}(r) \text{ is in } S_p \}$

where $p_i$ is a new propositional variable such that $p_i \notin B_P$ and $p_i \neq p_j$ if $i \neq j$. Then, build a d-program

$$P^\delta = (P \setminus \bigcup_{p \in B_P} R_P) \cup \bigcup_{p \in B_P} (S_p \cup D_p)$$

where $Q = (P \setminus \bigcup_{p \in B_P} R_P) \cup \bigcup_{p \in B_P} S_p$ is an SD program and $D = \bigcup_{p \in B_P} D_p$ is a set of d-rules.

$P^\delta$ introduces additional propositional variables and $B_P \subseteq B_{P^\delta}$ holds. By definition, the next result holds.

Proposition 1

Let $P$ be a definite program and $P^\delta$ its transformed d-program. Suppose that $P$ and $P^\delta$ have the least models $M$ and $M'$, respectively. Then $M = M' \cap B_P$ holds.

In this way, any definite program $P$ is transformed to a semantically equivalent d-program $P^\delta = Q \cup D$ where $Q$ is an SD program and $D$ is a set of d-rules. A d-program is represented by a matrix as follows.

Definition 7 (program matrix for d-programs)

Let $P^\delta$ be a d-program such that $P^\delta = Q \cup D$ where $Q$ is an SD program and $D$ is a set of d-rules, and $B_{P^\delta} = \{ p_1, \ldots, p_m \}$ the Herbrand base of $P^\delta$. Then $P^\delta$ is represented by a matrix $M_{P^\delta} \in \mathbb{R}^{m \times m}$ such that for each element $a_{ij}$, the next holds.

1. $a_{ij} = 1$ if $1 \leq k \leq l$, $1 \leq i, j \leq m$, $i \neq j$, $k \neq l$.
2. Otherwise, every rule in $Q$ is encoded as in Def. 3.

Given a program matrix $M_{P^\delta}$ and the initial vector $v_0$ representing facts in $P^\delta$, the fixpoint $v_k = \text{FP}(M_{P^\delta}v_0)$ ($k \geq 1$) is computed as before. The fixpoint represents the least model of $P^\delta$.

Theorem 2

Let $P^\delta$ be a d-program and $M_{P^\delta} \in \mathbb{R}^{m \times m}$ its program matrix. Then $m \in \mathbb{R}^m$ is a vector representing the least model of $P^\delta$ if $m = \text{FP}(M_{P^\delta}v_0)$ where $v_0$ is the initial vector of $P^\delta$.

By Proposition 1 and Theorem 2, we can compute the least model of any definite program.

Example 3

Consider the program $P = \{ p \leftarrow q, q \leftarrow p \land r, q \leftarrow s, s \leftarrow \}$. As $P$ is a non-SD program, it is transformed to a d-program $P^\delta = \{ p \leftarrow q \}$. $t \land r, u \leftarrow s, s \leftarrow, q \leftarrow t \lor u \}$ where $t$ and $u$ are new propositional variables. Then 

$$M_{P^\delta} \in \mathbb{R}^{6 \times 6}$$ becomes the matrix (right). The initial vector of $P^\delta$ is $v_0 = (0, 0, 0, 1, 0, 0)^T$. Then, $v_1 = \theta(\mathbf{M_{P^\delta}}v_0) = (0, 0, 0, 1, 0, 1)^T, v_2 = \theta(\mathbf{M_{P^\delta}}v_1) = (0, 1, 0, 1, 0, 1)^T, v_3 = \theta(\mathbf{M_{P^\delta}}v_2) = (1, 1, 0, 1, 0, 1)^T$, and $v_4 = \theta(\mathbf{M_{P^\delta}}v_3) = v_3$. Then $m = \text{FP}(M_{P^\delta}v_0) = (1, 1, 0, 1, 0, 1)^T$ represents the least model $\{ p, q, s, u \}$ of $P^\delta$, hence $\{ p, q, s, u \} \cap B_P = \{ p, q, s \}$ is the least model of $P$. 

\[\begin{pmatrix} p & q & r & s & t & u \\ 0 & 0 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 1/2 & 0 & 1/2 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \end{pmatrix}\]
Algorithm 1: Matrix Computation of Least Models

\textbf{Input:} a definite program \( P \) and its Herbrand base \( B_P = \{ p_1, \ldots, p_n \} \).
\textbf{Output:} a vector \( u \) representing the least model of \( P \).

\textbf{Step 1:} Transform \( P \) to a d-program \( P^\delta = Q \cup D \) with \( B_{p^\delta} = \{ p_1, \ldots, p_m \} \) where \( Q \) is an SD program and \( D \) is a set of d-rules.

\textbf{Step 2:} Embed \( P^\delta \) into a vector space.
- Create the matrix \( M_{p^\delta} \in \mathbb{R}^{m \times m} \) representing \( P^\delta \).
- Create the initial vector \( v_0 = (v_1, \ldots, v_m)^T \) of \( P^\delta \).

\textbf{Step 3:} Compute the least model of \( P^\delta \).
\[ \begin{align*}
    &v := v_0; \\
    &u := \theta(M_{p^\delta}v) \\
    \text{while } u \neq v \text{ do} \\
    &v := u; \\
    &u := \theta(M_{p^\delta}v) \\
    \text{end do} \\
    \text{return } u[1 \ldots n]
\end{align*} \]

Fig. 1. Algorithm for computing least models

An algorithm for computing the least model of a definite program \( P \) is shown in Figure 1. In the algorithm, the complexity of computing \( M_{p^\delta}v \) is \( O(m^2) \) and computing \( \theta(\cdot) \) is \( O(m) \). The number of times for iterating \( M_{p^\delta}v \) is at most \( (m+1) \times (m+m^2) = O(m^3) \) in the worst case.

### 3.3 Column Reduction

To decrease the complexity of computing \( M_{p^\delta}v \), we introduce a technique of column reduction of program matrices.

\textbf{Definition 8} (submatrix representation of d-programs)

Let \( P \) be a definite program such that \( |B_P| = n \). Suppose that \( P \) is transformed to a d-program \( P^\delta \) such that \( P^\delta = Q \cup D \) where \( Q \) is an SD program and \( D \) is a set of d-rules, and \( B_{p^\delta} = \{ p_1, \ldots, p_m \} \).

Then \( P^\delta \) is represented by a matrix \( \mathbf{N}_{p^\delta} \in \mathbb{R}^{m \times n} \) such that each element \( h_{ij} \) \((1 \leq i \leq m, 1 \leq j \leq n)\) in \( \mathbf{N}_{p^\delta} \) is equivalent to the corresponding element \( a_{ij} \) \((1 \leq i, j \leq m)\) in \( M_{p^\delta} \) of Def. 7. \( \mathbf{N}_{p^\delta} \) is called a submatrix of \( P^\delta \).

Note that the size of \( \mathbf{M}_{p^\delta} \in \mathbb{R}^{m \times m} \) of Def. 7 is reduced to \( \mathbf{N}_{p^\delta} \in \mathbb{R}^{m \times n} \) in Def. 8 by \( n \leq m \). In \( \mathbf{N}_{p^\delta} \), the columns do not include values of newly introduced propositions and derivation of propositions in \( B_P \) via d-rules is checked by the following \( \theta_D \)-thresholding.

\textbf{Definition 9} (\( \theta_D \)-thresholding)

Given a vector \( v = (a_1, \ldots, a_m)^T \), define a vector \( w = \theta_D(v) = (w_1, \ldots, w_m)^T \) such that (i) \( w_i = 1 \) \((1 \leq i \leq m)\) if \( a_i \geq 1 \), (ii) \( w_i = 1 \) \((1 \leq i \leq n)\) if \( \exists j w_j = 1 \) \((n + 1 \leq j \leq m)\) and there is a d-rule \( d \in D \) such that \( \text{head}(d) = p_i \) and \( \text{row}_j(w) \in \text{body}(d) \), and (iii) otherwise, \( w_j = 0 \). We call \( \theta_D(v) \) the \( \theta_D \)-thresholding of \( v \).

\( \theta_D(v) \) is computed by checking the value of \( a_i \) for \( 1 \leq i \leq m \) and checking all d-rules for \( n + 1 \leq j \leq m \). Since the number of d-rules is at most \( n \), the complexity of computing \( \theta_D(v) \) is \( O(m + (m - n) \times n) = O(m \times n) \). By definition, it holds that \( \theta_D(v) = \theta_D(\theta(v)) \).
Proposition 2
Let $P$ be a definite program with $B_P = \{p_1, \ldots, p_n\}$, and $P^\delta$ a transformed d-program with $B_{P^\delta} = \{p_1, \ldots, p_n, p_{n+1}, \ldots, p_m\}$. Let $N_{P^\delta} \in \mathbb{R}^{m \times n}$ be a submatrix of $P^\delta$. Given a vector $\mathbf{v} \in \mathbb{R}^n$ representing an interpretation $I$ of $P$, let $u = \theta_D(N_{P^\delta}\mathbf{v}) \in \mathbb{R}^m$. Then $u$ is a vector representing an interpretation $J$ of $P^\delta$ such that $J \cap B_P = T_P(I)$.

Given a program matrix $N_{P^\delta} \in \mathbb{R}^{m \times n}$ and the initial vector $\mathbf{v}_0 \in \mathbb{R}^m$ of $P^\delta$, define

$$v_1 = \theta_D(N_{P^\delta}\mathbf{v}_0[1 \ldots n]) \quad \text{and} \quad v_{k+1} = \theta_D(N_{P^\delta}v_k[1 \ldots n]) \quad (k \geq 1)$$

where $N_{P^\delta}v_k[1 \ldots n]$ represents the product of $N_{P^\delta}$ and $v_k[1 \ldots n]$. Then it is shown that $v_{k+1} = v_k$ for some $k \geq 1$. When $v_{k+1} = v_k$, we write $v_k = \text{FP}(N_{P^\delta}\mathbf{v}_0[1 \ldots n])$.

Theorem 3
Let $P$ be a definite program with $B_P = \{p_1, \ldots, p_n\}$, and $P^\delta$ a transformed d-program with $B_{P^\delta} = \{p_1, \ldots, p_n, p_{n+1}, \ldots, p_m\}$. Then $m \in \mathbb{R}^n$ is a vector representing the least model of $P$ iff $m = \text{FP}(N_{P^\delta}\mathbf{v}_0[1 \ldots n])$ where $\mathbf{v}_0 \in \mathbb{R}^m$ is the initial vector of $P^\delta$.

Generally, given a d-program $P^\delta$, the value $k$ of $v_k = \text{FP}(N_{P^\delta}\mathbf{v}_0[1 \ldots n])$ is not greater than the value $h$ of $\mathbf{v}_h = \text{FP}(\mathbf{M}_P\mathbf{v}_0)$ of Section 3.1.

Example 4
For the d-program $P^\delta$ of Example 3, we have the submatrix $N_{P^\delta} \in \mathbb{R}^{6 \times 4}$ representing $P^\delta$.

Given the initial vector $\mathbf{v}_0 = (0,0,0,1,0,0)^T$ of $P^\delta$, it becomes $v_1 = \theta_D(N_{P^\delta}\mathbf{v}_0[1 \ldots 4]) = (0,1,0,1,0,1)^T$, $v_2 = \theta_D(N_{P^\delta}v_1[1 \ldots 4]) = (1,1,0,1,0,1)^T$, $v_3 = \theta_D(N_{P^\delta}v_2[1 \ldots 4]) = (1,1,0,1,0,1)^T = v_2$. Then $v_2$ is a vector representing the least model of $P^\delta$, and $v_2[1 \ldots 4]$ is a vector representing the least model $\{p,q,s\}$ of $P$. Note that the second element of $v_i$ ($i = 1,2,3$) becomes 1 by Def. 9(ii).

By Proposition 2, we can replace the computation $u = \theta(\mathbf{M}_{P^\delta}\mathbf{v})$ in Step 3 of Algorithm 1 in Figure 1 by $u = \theta_D(N_{P^\delta}\mathbf{v}[1 \ldots n])$. In the column reduction method, the complexity of computing $N_{P^\delta}\mathbf{v}$ is $O(m \times n)$ and computing $\theta_D(\cdot)$ is $O(m \times n)$. The number of times for iterating $N_{P^\delta}\mathbf{v}$ is at most $(m+1)$ times. So the complexity of computing $u = \theta_D(N_{P^\delta}\mathbf{v}[1 \ldots n])$ is $O((m+1) \times (m \times n + m \times n)) = O(m^2 \times n)$. Comparing the complexity $O(m^2)$ of Step 3 in Algorithm 1, the column reduction reduces the complexity to $O(m^2 \times n)$ as $m \gg n$ in general.

4 Partial Evaluation

Partial evaluation is known as an optimization technique in logic programming (Lloyd & Shepherson 1991). In this section, we provide a method of computing partial evaluation of definite programs in vector spaces.

Definition 10 (partial evaluation)
Let $P$ be an SD program. For any rule $r$ in $P$, put $U_r = \{r_i \mid r_i \in P \text{ and } head(r_i) \in body(r)\}$. Then construct a rule $r' = \text{unfold}(r)$ such that

- $head(r') = head(r)$, and
- $body(r') = (body(r) \setminus \bigcup_{r_i \in U_r} \{head(r_i)\}) \cup \bigcup_{r_i \in U_r} body(r_i)$.
We define
\[ \text{peval}(\mathcal{P}) = \bigcup_{r \in \mathcal{P}} \text{unfold}(r) \]
and call it partial evaluation of \( \mathcal{P} \).

**Example 5**
Consider \( \mathcal{P} = \{ p \leftarrow q \land s \land t, \ q \leftarrow p \land t, \ s \leftarrow t, \ t \leftarrow \} \). Put \( r_1 = (p \leftarrow q \land s \land t), r_2 = (q \leftarrow p \land t), r_3 = (s \leftarrow t), \) and \( r_4 = (t \leftarrow) \). Unfolding rules produces: \( \text{unfold}(r_1) = (p \leftarrow p \land t \land t) = (p \leftarrow p \land t), \) \( \text{unfold}(r_2) = (q \leftarrow q \land s \land t), \) \( \text{unfold}(r_3) = (s \leftarrow), \) and \( \text{unfold}(r_4) = (t \leftarrow) \). Then it becomes \( \text{peval}(\mathcal{P}) = \{ p \leftarrow p \land t, \ q \leftarrow q \land s \land t, \ s \leftarrow, \ t \leftarrow \} \).

By definition, \( \text{peval}(\mathcal{P}) \) is obtained from \( \mathcal{P} \) by unfolding propositional variables appearing in the body of any rule in \( \mathcal{P} \) in parallel. Partial evaluation preserves the least model of the original program (Lloyd & Shepherdson 1991).

**Proposition 3**
Let \( \mathcal{P} \) be an SD program. Then \( \mathcal{P} \) and \( \text{peval}(\mathcal{P}) \) have the same least model.

Partial evaluation is computed by matrix products in vector spaces.

**Example 6**
The program \( \mathcal{P} \) of Example 5 is represented by the matrix \( \mathcal{M}_\mathcal{P} \), and \( (\mathcal{M}_\mathcal{P})^2 \) becomes
\[
\mathcal{M}_\mathcal{P} = \begin{pmatrix}
  p & q & s & t \\
  0 & 1/3 & 1/3 & 1/3 \\
  1/2 & 0 & 0 & 1/2 \\
  0 & 0 & 0 & 0 \\
  0 & 0 & 0 & 1
\end{pmatrix}
\]
\[
(\mathcal{M}_\mathcal{P})^2 = \begin{pmatrix}
  1/6 & 0 & 0 & 5/6 \\
  0 & 1/6 & 1/6 & 2/3 \\
  0 & 0 & 0 & 1 \\
  0 & 0 & 0 & 1
\end{pmatrix}
\]

Intuitively speaking, non-zero elements in \( (\mathcal{M}_\mathcal{P})^2 \) represent conjuncts appearing in each rule. So the first row represents the rule \( p \leftarrow p \land t \) and the second row represents the rule \( q \leftarrow q \land s \land t \). \( (\mathcal{M}_\mathcal{P})^2 \) then represents \( \mathcal{P}' = \{ p \leftarrow p \land t, \ q \leftarrow q \land s \land t, \ s \leftarrow t, \ t \leftarrow \} \). \( \mathcal{P}' \) is different from \( \text{peval}(\mathcal{P}) \) for the representation of the rule \( s \leftarrow t \). This is because \( t \leftarrow \) is represented as \( t \leftarrow \) in \( \mathcal{M}_\mathcal{P} \), so that unfolding \( s \leftarrow t \) by \( t \leftarrow \) becomes \( s \leftarrow t \). Thus, \( (\mathcal{M}_\mathcal{P})^2 \) does not represent the result of unfolding rules by facts precisely, while it does not affect the result of computing the least model of \( \mathcal{P} \). In fact, applying the vector \( v_0 = (0, 0, 0, 1)^T \) representing facts in \( \mathcal{P} \) and applying \( \theta \)-thresholding, we obtain \( \theta((\mathcal{M}_\mathcal{P})^2 v_0) = (0, 0, 1, 1) \) that represents the least model \( \{ s, t \} \) of \( \mathcal{P} \). We say that \( (\mathcal{M}_\mathcal{P})^2 \) represents the rule by rule (shortly, r-r) partial evaluation, and often say just partial evaluation when no confusion arises. Formally, we have the next result.

**Proposition 4**
Let \( \mathcal{P} \) be an SD program and \( v_0 \) the initial vector representing facts of \( \mathcal{P} \). Then \( \theta((\mathcal{M}_\mathcal{P})^2 v_0) = \theta(\mathcal{M}_\mathcal{P} \theta(\mathcal{M}_\mathcal{P} v_0)) \).

Partial evaluation has the effect of reducing deduction steps by unfolding rules in advance. Proposition 4 realizes this effect by computing matrix products in advance. Partial evaluation is performed iteratively as
\[
\text{peval}^k(\mathcal{P}) = \text{peval}(\text{peval}^{k-1}(\mathcal{P})) \quad (k \geq 1) \quad \text{and} \quad \text{peval}^0(\mathcal{P}) = \mathcal{P}.
\]
Iterative partial evaluation is computed by matrix products as follows.
Algorithm 2: Partial Evaluation

**Input:** a definite program $P$ and its Herbrand base $B_P$.

**Output:** a vector $u$ representing the least model of $P$.

**Step 1:** Transform $P$ to a d-program $P^\delta = Q \cup D$ where $Q$ is an SD program and $D$ is a set of d-rules.

**Step 2:** Embed $P^\delta$ into a vector space.
- Create the matrix $M_Q$ representing $Q$.
- Create the matrix $M_D$ representing $D$.

**Step 3:** Compute (r-r) partial evaluation of $Q$.

Let $P$ be an SD program and $M_P \in \mathbb{R}^{n \times n}$ its program matrix. Define $\Gamma_1 = (M_Q)^2$ and $\Gamma_{k+1} = (\Gamma_k)^2$ ($k \geq 1$). Then $\Gamma_k$ is a matrix representing a program that is obtained by $k$-th iteration of (r-r) partial evaluation.

**Theorem 4**

Let $P$ be an SD program and $\Gamma_k \in \mathbb{R}^{n \times n}$ ($k \geq 1$). Then $\theta(\Gamma_k v_0) = v_k$ where $v_k = \theta(M_P v_{k-1})$.

When $P$ is a non-SD program, first transform $P$ to a d-program $P^\delta = Q \cup D$ where $Q$ is an SD program and $D$ is a set of d-rules (Section 3.2). Next, define $\Gamma_k^\delta = \Gamma_k + M_D$. We then compute (r-r) partial evaluation of $P^\delta$ as (r-r) partial evaluation of an SD program $Q$ plus d-rules $D$.

An algorithm for computing the least model of a definite program $P$ by (r-r) partial evaluation is shown in Figure 2. We can combine partial evaluation and column reduction of Section 3.3 by slightly changing Step 3 of Algorithm 2. We evaluate this hybrid method in the next section.

**5 Experimental Results**

In this section, we compare runtime for computing the least model of a definite program. The testing is done on a computer with the following configuration:

- Operating system: Linux Ubuntu 16.04 LTS 64bit
- CPU: Intel Core i7-6800K (3.4 GHz/14nm/Cores=6/Threads=12/Cache=15MB), Memory 32GB, DDR-2400
- GPU: GeForce GTX1070TI GDDR5 8GB

Let $P$ be an SD program and $M_P \in \mathbb{R}^{n \times n}$ its program matrix. Define $\Gamma_1 = (M_P)^2$ and $\Gamma_{k+1} = (\Gamma_k)^2$ ($k \geq 1$). Then $\Gamma_k$ is a matrix representing a program that is obtained by $k$-th iteration of (r-r) partial evaluation.
Input: a definite program $P$.
Output: the least model of $P$.

$I := \text{set of facts in } P$;
$J := \emptyset$;
while ($I \neq J$) do
  $J := I$;
  for $r$ in $P$ do
    if $\text{body}(r) \subseteq J$ then $I := I \cup \{\text{head}(r)\}$;
  end do
return $J$

Fig. 3. Algorithm for computing least models by $T_P$-operator

- Implementation language: Maple 2017, 64 bit\(^4\)

Given the size $n = |BP|$ of the Herbrand base $BP$ and the number $m = |P|$ of rules in $P$, rules are randomly generated as in Table 1.

Table 1. Proportion of rules in $P$ based on the number of propositional variables in their bodies

<table>
<thead>

<td>4%</td>
<td>2%</td>
<td>0-1%</td>
</tr>
</tbody>
</table>

A definite program $P$ is randomly generated based on $(n,m)$. We set those parameters as $n \ll m$, so generated programs are non-SD programs and they are transformed to d-programs.

We compare runtime for computing the least model of $P$ by the following four methods: (a) computation by the $T_P$-operator; (b) computation by program matrices; (c) computation by column reduction; and (d) partial evaluation. Computation by the $T_P$-operator is done by the procedure in Figure 3. Computation by program matrices is done by Algorithm 1, and computation by column reduction is done by modifying Step 3 of Algorithm 1 (see Sec. 3.3). In partial evaluation, the input parameter $k$ of Algorithm 2 is set as $k = 1, 5, \frac{n}{2}, n$ where $n = |BP|$. We then compute a vector representing the least model of $P$ in two ways: program matrices and column reduction.

We perform experiments by changing parameters $(n,m,k)$. For each $(n,m,k)$ we measure runtime at least three times and pick average values. Tables 2, 3 and 4 show the results of testing for $n = 50, 100$ and $200$, respectively. In the table, “all” means time for creating a program matrix and computing a fixpoint, and “fixpoint” means time for computing a fixpoint. Figure 4 compares runtime for computing fixpoints.

By those tables, we can observe the following facts.

- For fixpoint computation, column reduction outperforms matrix computation and the $T_P$-operator in almost every cases. Naive computation by program matrices becomes inefficient in large scale of programs.

\(^4\) Maple 2017 supports to use GPU for accelerating linear algebraic computation by CUDA package (Maple 2017). The experimental results in this section do not use the CUDA package, however.
• Column reduction is effective in a large scale of programs. It is often more than 10 times faster than naive computation by program matrices.

• By performing partial evaluation, time for fixpoint computation is significantly reduced. In particular, partial evaluation + column reduction is effective when \( k > 1 \), and fixpoint computation by this hybrid method is often more than 10 times faster than other methods in large scale of programs (Tables 3 and 4).

6 Conclusion

In this paper, we introduced a method of embedding logic programs in vector spaces. We developed algorithms for computing least models of definite programs, and presented column reduction and partial evaluation for optimization. Experimental results show that column reduction is effective to realize efficient computation in a large scale of programs and partial evaluation helps to reduce runtime significantly. It is known that the least model of a definite program is computed in \( O(N) \) (Dowling & Gallier 1984) where \( N \) is the size (number of literals) of a program. Since column reduction takes \( O(m^2 \times n) \) time, it would be effective when \( m^2 \times n < N \), i.e., the size of a program is large with a relatively small number of atoms. Moreover, since partial evaluation is performed apart from fixpoint computation, combination of column reduction and partial evaluation would be effective in practice. The linear algebraic approach enables us to use efficient algorithms of numerical linear algebra and opens perspective for parallel computation of logic

programming. Performance of our implementation heavily depends on the environment of linear algebraic computation. For instance, we could use the CUDA package to accelerate linear algebraic computation on GPU. Once more powerful platforms are developed for linear algebraic computation, the proposed method would have the merit of such advanced technologies. We have used Maple for implementation, but the proposed algorithms can be realized by other programming languages. We compared runtime in experiments, while it would be interesting to compare other metrics in algorithms and matrices that are part of the computation, for instance, the number of iterations to the fixpoint, the compression $(m-n)/m$ achieved by column reduction, the sparseness of the matrices with and without partial evaluation, and so on.

This paper studies algorithms for computing least models of definite programs. An impor-
tant question is whether linear algebraic computation is applied to answer set programming. A method for computing stable models of normal logic programs was reported in (Sakama et al. 2017) in which normal programs are represented by third-order tensors. Computing large scale of programs in third-order tensors requires scalable techniques and optimization, however. As an alternative approach, we can use a technique of transforming normal programs to definite programs, and computing stable models as least models of the transformed programs (Alferes et al. 2000). A preliminary report based on this method is under preparation (Nguyen et al. 2018), and partial evaluation would help to reduce runtime. We also plan to develop a new algorithm for ASP in vector spaces and evaluate it using benchmark testing. Recently, Sato et al. (2018) introduce a method of linear algebraic computation of abduction in Datalog. We consider that abductive logic programming would be realized in vector spaces by extending the framework introduced in this paper. There is a number of interesting topics to be investigated and rooms for improvement in this new approach to logic programming.
